Postprandial Lipid Abnormalities in Type 2 Diabetes Mellitus

SV Madhu*, V Mittal**, B Krishna Ram***, DK Srivastava****

Abstract

Aim and Objectives: To study the postprandial lipid abnormalities in patients with type 2 diabetes mellitus.

Material and Methods: Postprandial lipids were studied in 20 male type 2 diabetic subjects (age 49.75 ± 4.82 years) and 20 age and sex matched healthy controls (age 49.55 ± 4.82 years) after an oral fat challenge which consisted of a meal providing 729 kcal/m² body surface area with 68 gm fat.

Results: Average duration of diabetes among diabetic was 2.32 ± 3.03 years. The body mass index (cases 25.84 ± 4.52; controls 25.74 ± 5.0; p > 0.05) and waist-hip ratio (cases 1.06 ± 0.13; controls 1.14 ± 0.2; p > 0.05) were similar in both groups. While fasting serum lipids were not significantly different between the two groups, a number of serum lipid abnormalities were noted in type 2 diabetic subjects in the postprandial state. These included a higher triglyceride-area under curve (AUC) (cases 1298.08 ± 485.2 vs. controls 922.15 ± 390.47 mg/dl/8h; p=0.01), a higher triglyceride-area under incremental curve (AUIC) (cases 549.68 ± 382.24; control 294.75 ± 172.6 mg/dl/8h; p=0.01), a higher peak triglyceride level (cases 425.2 ± 204.47 mg%, controls 283.9 ± 11.6.94 mg%, p=0.01), a lower HDL-AUC (cases 130.35 ± 33.55 vs. controls 168.48 ± 56.01 mg/dl/8h, p=0.013) and a lower HDL nadir (Cases 28.05 ± 10.94 mg%, controls 37.13 ± 13.52 mg%, p < 0.02). Triglyceride AUC correlated significantly with fasting serum triglyceride (r=0.62) and BMI (r=0.7), but not with waist hip ratio or fasting serum insulin levels. Postprandial lipaemia did not correlate with age, duration of diabetes, fasting blood glucose or glycosylated hemoglobin.

Conclusion: In conclusion, make type 2 diabetics demonstrate significant postprandial lipid abnormalities, particularly of triglycerides, which appear to be independent of glycaemic control.

INTRODUCTION

Type 2 diabetes mellitus is associated with the development of premature arteriosclerosis and a higher cardiovascular morbidity and mortality.1,2 Diabetic dyslipidaemia is believed to play an important role in the pathogenesis of accelerated atherosclerosis in this condition.3,4 The predominant lipid abnormalities seen in diabetes mellitus are an elevated serum triglyceride (Tg) level and a low HDL-C level.6 While several studies have found a significant association of fasting hypertriglyceridaemia7,8 and coronary artery disease (CAD) in diabetes mellitus, the relationship is not consistent particularly after adjusting for fasting HDL-C Levels.9

It is being increasingly believed that atherosclerosis is a postprandial phenomenon as at least with respect to lipids, we are in the postprandial phase for most of the day.10,11,12 High postprandial triglycerides have shown a strong and independent association with CAD.11,12 Earlier studies of postprandial lipids in diabetes mellitus have suggested abnormalities of Tg metabolism13,14 secondary to insulin resistance15 although results have not been consistent.16 We have examined the postprandial lipid responses to a standard fat challenge in diabetic patients to characterize the nature and extent of postprandial lipaemia among Indians with known high levels of insulin resistance.17

MATERIAL AND METHODS

An oral fat challenge was given to 20 male type 2 diabetic patients and 20 age, sex and BMI matched healthy controls who had no family history of diabetes. Diabetes was diagnosed as per revised ADA criteria and were either newly diagnosed or off treatment for 2 weeks.

Patients with fasting triglyceride level (FTG) > 250 mg/dl, nephropathy, hepatic disease, hypothyroidism, Cushing’s disease, inherited disorders of lipid metabolism, clinical or ECG evidence of CAD, alcoholism, smoking or use of medication affecting lipids...
were excluded. An oral glucose tolerance test was performed in all healthy controls to rule out diabetes, Impaired Fasting Glucose (IFG) and Impaired Glucose Tolerance (IGT). All subjects diabetic patients and control were hospitalised after preliminary clinical & lab assessment. These included fasting plasma glucose (FPG), 2 hrs postprandial plasma glucose (PPPG), Glycosylated Hemoglobin, lipid profile, kidney & liver function tests, X-ray chest and an electro cardiogram. After a 14 hour overnight fast, a standardised meal was given to all subjects providing 729 kcal/sq m body surface area (BSA) (65.2g fat/sq. m BSA; PUFA: SFA = 0.06; 240 mg cholesterol). Blood was drawn at 0, 2, 4, 6 and 8 hours for glucose, insulin and lipids estimation. Serum was separated and stored at - 20oc for various estimations.

RESULTS

Table 1 shows the baseline characteristics of patients with type 2 diabetes mellitus. Diabetic subjects were middle aged (mean age 49.75 ± 8.86 years), with a mean body mass index (BMI) of 25.84 ± 4.52 kg/sq m and waist/hip ratio of 1.06 ± 0.13 suggestive of central obesity. Diabetic subjects were matched for age, BMI, waist/hip ratio and fasting insulin levels with controls.

The fasting lipid profile in type 2 diabetes patients (Table 2) differed from controls only in a significantly lower HDL-C value (35.15 ± 10.84 mg/dl vs. 42.9 ± 14.11 mg/dl). There was no significant difference in any of the other lipid parameters in the fasting state.

Significant postprandial lipid abnormalities were observed in the diabetic subjects particularly of Tg and HDL-C (Table 3). Triglyceride area under the curve, postprandial triglyceride area under incremental curve and peak postprandial triglyceride levels were all significantly higher in diabetic subjects compared to controls (Figs. 1 and 2). In the case of HDL-C, while the HDL-C nadir and HDL-C Area under the curve were significantly lower than controls there was no difference once adjustment was made for fasting HDL-C values and area under decremental curves were compared.

Table 4 shows the correlation of postprandial triglyceride parameters with various baseline variables. Clearly, postprandial triglyceridaemia showed significant correlation only with BMI and fasting Tg values but not with age duration of diabetes or any other measure of glycemic (FPG, PPPG and HbA,c), or insulin resistance (W/H and fasting insulin level).

DISCUSSION

The present study clearly demonstrates an altered postprandial (PP) response of serum triglycerides (Tg) following oral fat challenge in male type 2 diabetes subjects compared to controls. The PP hypertriglyceridaemia remained significant even after adjusting for fasting Tg levels and was present despite similar fasting Tg levels in diabetic patients and controls. To the best of our knowledge, this is the first report of abnormal postprandial triglyceridaemia among diabetic patients from India and highlights that at least in diabetic subjects, estimating lipids in the postprandial phase may be far more important than in the fasting phase.
Exaggerated PP triglyceridaemic responses have been shown in patients with diabetes mellitus by few\textsuperscript{13,14} while other have failed to demonstrate such a difference.\textsuperscript{16} However, these responses were observed only in diabetic patients whether obese\textsuperscript{13} or non obese,\textsuperscript{16} who displayed moderate fasting hypertriglyceridaemia. Once diabetic subjects were matched with controls for fasting Tg levels in addition to age, gender and body mass index then PP hypertriglyceridaemia too was not significantly different.\textsuperscript{16} In general, the relationship between fasting Tg and postprandial lipaemia in patients with NIDDM was similar to that in non-diabetic individuals.\textsuperscript{14}

PPTg responses significantly correlated with fasting Tg concentration in the diabetic group suggesting higher the fasting Tg Concentration greater was the degree of PP lipaemia.\textsuperscript{16} Whether it is the fasting Tg level which determines PPTg level in these patients as interpreted by previous workers or it is the magnitude of the PPTg response that determines the fasting Tg level, is not very clear. On the basis of our findings, as well as others it would appear that it is the PP triglyceridaemia that determines fasting Tg levels. The postprandial Tg levels peaked at 6-8 hrs after a high fat meal and still remained close to the peak in most patients even after 8 hrs. Fasting Tg levels estimated 12-14 hrs after the previous meal would thus represent the Tg value recorded on the down slope of the PPTg response curve 4-6 hours after its peak.

The diabetic state itself appears to be a major factor contributing to the abnormal PPTg response among type 2 diabetic patients as other confounders of altered PP lipid responses such as age, sex, body mass index and measures of central obesity have been carefully controlled in this study. Earlier studies have reported that postprandial lipid metabolism could by altered by factors such as obesity,\textsuperscript{13} insulin resistance,\textsuperscript{15} age\textsuperscript{18} and visceral obesity.\textsuperscript{19} The influence of diabetic state on PP triglyceride metabolism even after controlling for obesity has not been reported earlier. This effect however, seems to be independent of current or previous glycemic control, as we did not find a significant correlation of PP lipaemia with any of the glycemic parameters studied. Obesity also appears to influence PP lipaemia in type 2 DM as high PP triglyceridaemia showed good correlation with body mass index. Thus, it would appear that the magnitude of PP Tg response in type 2 diabetic subjects is largely determined by an interaction of obesity and the underlying diabetic state.

Insulin resistance has been shown to be important in regulating the postprandial concentration of triglycerides and triglycerides rich lipoproteins (TRL).\textsuperscript{15} The current study found no correlation of fasting insulin level or waist/hip ratio, both considered to be markers of insulin resistance, with PP lipaemic response parameters. These findings would seem to argue against a major role of insulin resistance in postprandial fat metabolism at least in diabetic subjects. However, caution is needed while interpreting fasting insulin levels as a reliable indicator of insulin resistance in type 2 diabetes mellitus patients as these values would also be affected by variation in insulin secretory reserve in such patients as well as by the concomitant use of insulin secretagogues in them.

Several underlying mechanisms have been postulated for the exaggerated PPTg response in diabetes mellitus. Although, this has not been resolved completely, delayed clearance of TRL secondary to decreased LPL activity is believed to be the most important mechanism with some contribution from excessive hepatic Tg production.\textsuperscript{20,21}
In conclusion, Male type 2 diabetic patients demonstrate significant postprandial triglyceride abnormalities which appear to be independent of glycemic control.
